Lecture 10. **Surface Energy Balance** (Garratt 5.1-5.2)

The balance of energy at the earth’s surface is inextricably linked to the overlying atmospheric boundary layer. In this lecture, we consider the energy budget of different kinds of surfaces. Consider first an ideal surface, which is a very thin interface between the air and an underlying solid or liquid medium that is opaque to radiation. Because it is thin, this surface has negligible heat capacity, and conservation of energy at the surface requires that

\[ R_N = H_S + H_L + H_G. \]

where (note sign conventions)

- \( H_S \) (often just called \( H \)) is the upward surface sensible heat flux
- \( H_L = LE \) is the upward surface latent heat flux due to evaporation at rate \( E \)
- \( H_G \) is the downward ground heat flux into the subsurface medium.
- \( R_N \) is the net downward radiative flux (longwave + shortwave).

The ratio \( B = H_L/H_S \) is called the **Bowen ratio**. \( L = 2.5 \times 10^6 \text{ J kg}^{-1} \) is the latent heat of vaporization.

Over land, there is a large diurnal variation in the surface energy budget (see schematic below). Over large bodies of water, the large heat capacity of the medium and the absorption of solar radiation over a large depth combine to reduce the near-surface diurnal temperature variability, so \( H_S \) and \( H_L \) vary much less. However, the surface ‘skin temperature’ of a tropical ocean can vary diurnally by up to 3 K in sunny, light-wind conditions.

An ideal surface is not usually encountered. Real surfaces may include a plant canopy or other features such as buildings not opaque to radiation and with a significant heat capacity. In this case, it is more appropriate to define an interfacial layer which includes such features. We let \( W(t) \) be the energy stored within this layer per unit horizontal area. The revised layer energy budget is:

\[ R_N = H_S + H_L + H_G + \frac{dW}{dt}. \]

We could also consider the energy budget of control volumes with finite horizontal extent (e.g., a parking lot, city, or larger geographic region). In this case horizontal transfer of energy may also be important; we won’t consider this complication here.

![Fig. 2.1](image)

2 Heat Budget at the Surface

Picture a layer of air with its top just above the highest trees (or ocean wave crests) in region, and its base just below the earth's surface (or below the wave troughs), as sketched in Fig 7.2a. This layer has turbulent energy transfer with the air above it, radiative transfer through the top of it, and molecular energy transfer into the soil (or sea) below.

The energy budget for this layer, where upward fluxes are positive, is:

\[ -Q_s^* = Q_H + Q_E - Q_G + \Delta Q_S \]  
\[ Q_s^* = Q_H + Q_E - Q_G + \Delta Q_S \]

where
- \( Q_s^* \) = net upward radiation at the surface
- \( Q_H \) = represents the upward sensible heat flux out of the top
- \( Q_E \) = represents the upward latent heat flux out of the top
- \( Q_G \) = represents the upward molecular heat flux into the bottom
- \( \Delta Q_S \) = denotes the storage or intake of internal energy (positive for warming and for chemical storage by photosynthesis).

In simple terms, this is nothing more than energy in balancing energy out and storage. The external forcing is \( Q_s^* \), and all the other terms are response terms.
Examples

The energy budget measured over a dry desert lake bed is shown above. In this case, latent heat fluxes are negligible. During the day, copious solar radiation is absorbed at the surface, and the ground heats up rapidly. Initially, most of the heat is conducted down into the soil, but as the layer of warmed soil thickens, $H_S$ dominates; the heat is primarily transferred to the air. This is promoted by extreme differences (up to 28 K) between the ground temperature and the 2 m air temperature. At night, surface radiative cooling is balanced by an upward ground heat flux. Since the nocturnal boundary layer is very stable, the turbulent heat flux $H_S$ is negligible.

The energy budget of a barley field is shown below. During the daytime, radiative heating of the surface is balanced mainly by latent heat flux due to evapotranspiration, i.e. evaporation from the soil surface and transpiration by the plant leaves. In the lingo, the Bowen ratio is small, -0.3 to 0.3. $H_L$ can be so large that the surface gets cooler than the air during early morning and late afternoon and the heat flux is downward. For a field, heat storage is usually negligible. At night, all terms become much smaller; as before, radiative cooling is mainly balanced by ground heat flux.

The last example is a Douglas fir forest (next page). Here latent and sensible heat fluxes are comparable during the day. The storage and ground heat flux are lumped in the curves, but for deep forest, the storage term dominates. At night, release of heat from the tree canopy and condensation (dew) balance radiative energy loss.

Net radiation at the surface

The net radiation $R_N$ is due to the difference between downwelling and upwelling shortwave plus longwave radiative fluxes. The net shortwave flux depends on the incident solar radiation $R_{s\downarrow}$ and on surface albedo $a_s$. The net longwave flux depends upon the downwelling longwave radiation $R_{L\downarrow}$, the surface emissivity $\varepsilon_s$, and the radiating temperature $T_s$:

$$R_N = R_{s\downarrow} - R_{s\uparrow} + R_{L\downarrow} - R_{L\uparrow} = (1-a_s)R_{s\downarrow} + R_{L\downarrow} - \{(1-\varepsilon_s)R_{L\downarrow} + \varepsilon_s\sigma T_s^4\}$$

Thus, the surface characteristics critically influence $R_N$. A table of typical surface radiative characteristics is given below. Albedos are quite diverse, while emissivities are usually near, but not equal, to 1.

An example of the surface radiation components is shown above.

**Soil temperatures and heat flux**

The surface or skin temperature is important for the radiative balance of the surface and for predicting frost and dew. It can be quite different than the ‘surface’ air temperature, which is conventionally measured at 1.5-2 m. In fact, it can be difficult to even measure *in situ* because it is difficult to shield and ventilate a sensor placed at the surface. Furthermore, if there is a plant canopy or surface inhomogeneity, there is no single uniquely definable surface temperature. Radiatively, an apparent surface temperature can be determined from the upward longwave energy flux if the emissivity is known. Large diurnal variations in skin temperature are achieved for bare, dry surfaces in clear calm conditions. Under such conditions, midday skin temperature may reach 50-60 C, while early morning skin temperatures can drop to 10-20 C.

The surface temperature is related to the profile of temperature in the subsurface medium, as illustrated in the figures on the next page. In a solid medium, the subsurface temperature profile is governed by heat conduction. Deeper in the soil, the diurnal temperature cycle decreases and lags the cycle of skin temperature. Over an annual cycle, similar waves penetrate further into the soil.

If $z$ is depth into the soil and $T(z, t)$ is soil temperature, Fourier’s law of heat conduction states:

$$H_G = -k \frac{\partial T}{\partial z}, \quad (k = \text{thermal conductivity})$$

Thermal energy conservation implies that

$$\rho c \frac{\partial T}{\partial t} = -\frac{\partial H_G}{\partial z}, \quad (\rho = \text{density}, \ c = \text{heat capacity})$$

Combining these two equations and assuming that the subsurface medium is homogeneous, so that material constants do not depend on $z$, we obtain the diffusion equation
An example of the surface radiation components is shown above.

\[
\frac{\partial T}{\partial t} = \kappa \frac{\partial^2 T}{\partial z^2} \quad (\kappa = k/\rho c = \text{thermal diffusivity}) \quad (1)
\]

A table of material properties is given below; the thermal conductivity varies over almost two orders of magnitude from new snow (low) to rock (high). Wet soils have conductivities about five times as large as dry soils. The thermal diffusivity shows similar trends, but less variation. Surprisingly, \( \kappa \) is smallest for water due to its large heat capacity.

It is illuminating to look at a soil temperature wave forced by a sinusoidal variation in surface temperature. We assume a deep soil temperature \( T(z \to \infty) = \bar{T} \) and take \( T(0) = \bar{T} + A \cos \omega t \). We look for a solution to (1) that is also sinusoidal in time with the same frequency \( \omega \):

\[
T(z, t) = \bar{T} + \Re \{a(z)\exp(i\omega t)\}
\]

Here \( a(z) \) is a complex-valued function of \( z \). To satisfy (1):

\[
\omega a = -\kappa \frac{\partial^2 a}{\partial z^2} \quad (2)
\]

To satisfy the boundary conditions,

\[
a(0) = A, \quad a(z \to \infty) = 0
\]

The solution of (2) that satisfies the BCs is

\[
a(z) = A \exp(-[1 + i]z/D), \quad D = (2\kappa/\omega)^{1/2}
\]
Data for clay and sand are approximately consistent with Eq. A24, in which \( C_m \) is equal to \( 2.7 \times 10^6 \) and \( 2.2 \times 10^6 \) J m\(^{-3}\) K\(^{-1}\) for clay and sand respectively; \( C_m \) is equal to \( \rho_w c_1 \), with \( \rho_w = 1000 \) kg m\(^{-3}\) and \( c_1 = 4186 \) J kg\(^{-1}\) K\(^{-1}\); and \( \eta \) is taken from Table A9. The reader should also consult e.g. Geiger (1965, Table 10), Hillel (1982, Table 9.3) and Oke (1987, Table 2.1).

### Table A7. Representative values of the thermal conductivity \( k_s \), specific heat \( c_s \), density \( \rho_s \), and thermal diffusivity \( \kappa_s \) for various types of surface based mainly on Table 11-3 in Pielke (1984)

</table>

A table of material properties is given below; the thermal conductivity varies over almost two orders of magnitude from new snow (low) to rock (high). Wet soils have conductivities about five times as large as dry soils. The thermal diffusivity shows similar trends, but less variation. Surprisingly, \( \kappa \) is smallest for water due to its large heat capacity.

It is illuminating to look at a soil temperature wave forced by a sinusoidal variation in surface temperature. We assume a deep soil temperature \( T(z \to \infty) = \bar{T} \) and take \( T(0) = \bar{T} + A \cos \omega t \). We look for a solution to (1) that is also sinusoidal in time with the same frequency \( \omega \):

\[
T(z, t) = \bar{T} + \text{Re}\{a(z)\exp(i\omega t)\}
\]

Here \( a(z) \) is a complex-valued function of \( z \). To satisfy (1):

\[
\text{Re}\{a(z)\exp(i\omega t)\} = \frac{2}{\kappa} \left. \frac{\partial T}{\partial z^2} \right|_{z=0}
\]

To satisfy the boundary conditions,

\[
a(0) = A, \quad a(z \to \infty) = 0
\]

The solution of (2) that satisfies the BCs is

\[
a(z) = A \exp(-[1 + i]z/D), \quad D = (2\kappa/\omega)^{1/2}
\]
In the case of sinusoidal forcing, we take the upper boundary condition (at $z = 0$) to be 

$$T(0, t) = \mathcal{T} + A \cos \omega t,$$

where $T(0, t)$ is the surface temperature, $A$ is the surface temperature amplitude, $\mathcal{T}$ is the average surface temperature and $\omega$ is the angular frequency. For the lower boundary condition, we assume that the deep soil temperature is equal to the average surface temperature: $T(\infty, t) = \mathcal{T}$. A general solution to (3) is 

$$T(z, t) = \mathcal{T} + \text{Re} \{a(z) \exp(i\omega t)\},$$

where $a(z)$ is a complex amplitude. Substitute (4) into (3) to get 

$$i\omega a = -\kappa \frac{d^2 a}{dz^2}.$$

To satisfy the boundary conditions on $T$, we require $a(0) = A$ and $a(z \to \infty) = 0$. 

2
The solution of (5) that satisfies the boundary conditions on \( a \) is
\[
a(z) = A \exp \left( -[1 + i] \frac{z}{D} \right),
\]
where \( D \) is referred to as the *damping depth* and is given by
\[
D = (2\kappa/\omega)^{1/2}.
\]
Now use (6) in (4), \( e^a e^b = e^{a+b} \), and \( \exp(ix) = \cos(x) + i \sin(x) \) to obtain
\[
T(z, t) = \bar{T} + A \exp(-z/D) \cos(\omega t - z/D).
\]
This solution is shown above. The temperature wave damps exponentially with depth \( z \), and lags the surface temperature wave by a phase \( z/D \), which increases with depth (see observations at bottom of page). The damping depth \( D \) to which the temperature wave penetrates increases as the oscillation frequency slows and is larger if the thermal diffusivity is larger. For moist soil (\( \kappa = 0.8 \times 10^{-6} \) m\(^2\) s\(^{-1}\)), \( D = 0.14 \) m for the diurnal cycle and 2.8 m for the annual cycle.

The ground heat flux at the surface is

\[
H_G = -k \partial T/\partial z(0) = -kA/D \Re\{[1 + i] \exp(\omega t)\} = \rho c(\kappa \omega)^{1/2} \cos(\omega t + \pi/4)
\]

It leads the surface temperature wave by 1/8 cycle. Hence, the ground heat flux is largest three hours ahead of the surface temperature for a diurnally varying surface temperature cycle.

In practice, the diurnal cycle of surface temperature is not sinusoidal. Furthermore, the surface temperature interacts with the sensible and latent heat fluxes so that the surface boundary condition is really the energy balance of the surface, which is coupled to the atmosphere. Lastly, testing of these formulas is complicated by the fact the temperature within 1 cm of the ground can be non-uniform, so the surface temperature and ground heat flux must be inferred from measurements.
This solution is shown above.
